Resumen

El proyecto busca realizar análisis y calibración de los datos de luminosidad correspondiente a las mediciones hechas por el experimento CMS para la recta final de la Run 3, durante 2025. Se utiliza para la medición el método PCC (por sus siglas en inglés, Pixel Cluster Counting) que consiste en el conteo de grupos de píxeles activados en el detector. Esto nos permitirá medir con precisión el valor de luminosidad para los datos recabados durante este año. La luminosidad y su incertidumbre sistemática son parámetros de suma importancia para las mediciones de física realizadas en los experimentos en el LHC.

Abstract

The project seeks to analyze and calibrate the luminosity corresponding to the measurements made by the CMS experiment for the final stretch of run 3, during 2025. The method used to measure this is Pixel Cluster Counting (PCC), which consists in counting groups of activated pixels in the detector. This will let us measure with precision the value of the luminosity parameter for data collected this period. Along with its systematic uncertainty, luminosity are parameters of utmost importance for physics measurements in LHC experiments.

1 BACKGROUND

The fundamental forces are the most elemental known interactions in nature, and the four recognized are gravity, electromagnetism, and the weak and strong forces. Gravity and electromagnetism are long-range interactions, and thus easily noticeable, while the weak and strong forces are essential to describe interatomic interactions. Particle physics, also referred as high energy physics, are in charge of studying said interactions, in addition to the fundamental particles that form all matter, and the standard model (SM) has been the most successful theoretical model, describing with precision these forces, with the important exception of gravity. The SM is separated between bosons, which are known as the mediators of the aforementioned forces, and fermions, consisting of elementary particles that compose every other particle.

In the fermionic sector, leptons and quarks fall into three generations: first generation has the up (u) and down (d) quarks, as well as the electron and electron neutrino; second generation consists of charm (c) and strange (s) quarks, muon and muon neutrino; and the third generation contains the top (t) and bottom (b), plus the tau and tau neutrino. Each one of these has its corresponding antiparticle, having their properties (such as charge) reversed in sign.

On the other hand, the bosonic sector is composed of the gauge bosons, which mediate every interaction: the gluon (g) for the strong nuclear force, W^\pm and Z^0 bosons for weak nuclear force, and the photon (γ) for electromagnetic force. The model also includes the Higgs boson (H), which is the way to account for the mass of other SM particles, via electroweak symmetry breaking mechanism [1].

Particles on the heavier side, such as the Higgs boson and the top quark (which were in fact, the last to be discovered), need a really high energy particle collider to be produced, like the Large Hadron Collider (LHC), that operates at a center-of-mass energy of 13.6 TeV in Geneva, Switzerland. It took multiple experiments, different colliders, and several years of upgrades on a long term plan to reach such high energies. So, it is indisputable that the energy of collision is one the most important parameter at particle colliders, but it is of similar significance to discuss and improve another parameter, called Luminosity.

Luminosity measures the number of useful events in a collider experiment. Instantaneous luminosity shows the ability of a particle accelerator to produce said interactions. It is the process-independent ratio between the rate of events per second $R(t)$, and the cross section of the process σ_p , and its defined by

$$R = \mathcal{L}_{inst} \cdot \sigma_p \quad (1)$$

To evaluate the total number of events, the integrated luminosity is used. It measures the collected data size, and characterizes the performance of an accelerator, given by:

$$\mathcal{L}_{int} = \int_0^t \mathcal{L}(t') dt' \quad (2)$$

During Run 1 (2011-2012) LHC reached a peak instantaneous luminosity of $0.77 \times 10^{34} \text{ cm}^{-2}\text{s}^{-1}$ and delivered an integrated luminosity of about 25 fb^{-1} with a precision of about 2.0%¹. In the first part of Run 2 (2015-2016), the delivered luminosity has been measured to be 38.4 fb^{-1} with an unprecedented precision of 1.3% [2]. For the second part of Run 2 (2017-2018), the integrated luminosity is about 78 fb^{-1} , but its precise value and uncertainty remain to be determined [3]. On the current LHC/HL-LHC plan, Run 3 began in 2022 and is planned to last until the first half of 2026, expecting an integrated luminosity of about 500 fb^{-1} , as seen in figure 1.

Figure 1: CERN's current plan for reaching the High Luminosity LHC. The Long Shutdown 3 (LS3) is now scheduled starting July 2026, seven and a half months later than planned, and with a duration increased by four months. The start of Run 4 is now programmed for 2030 [?].

¹1 barn is a unit of area corresponding to 10^{-24} cm^2 and 1 femtobarn (fb) = 10^{-39} cm^2 . For comparison, the total Higgs production cross section is 48600 fb.

CERN's LHC has four major colliding points, each one with its respective detector: CMS, ATLAS, ALICE and LHCb. The detector that will be worked here corresponds to the CMS, which stands for Compact Muon Solenoid, and its experiment has the general objective to investigate a wide range of physics within the standard model and beyond, primarily with proton collisions.

The detector uses a powerful magnet to bend charged particles as they leave the point of collision, allowing to analyze its curvature to identify charge and measure their momentum. A silicon tracker, consisting of about 75 million sensors arranged in concentric layers, is in charge of measuring said curvature with high precision. It has the form of multiple cylindrical layers, and a large number of components. The electromagnetic calorimeter detects photons and electrons while the hadron calorimeter detects mostly pions (π) and kaons (K). Muons (μ) are detected by special chambers outside the solenoid, as shown in .

The CMS silicon pixel detector consists of four concentric cylindrical layers and three disks on each end, placed at certain distances from the center of the detector. The detector consists of 1856 sensor modules, and gives complete coverage over the interaction point, resulting in precise tracking. This yields a large amount of total pixels, so, adding the sensor's fine granularity, the hit occupancy is very low. Due to this, the Pixel Cluster Counting (PCC) method brings forth a linear function of pile up, which is an essential property of a luminometer. The PCC method has been used as one of main luminometers for more than a decade, showing its reliability.

2 OBJECTIVE

The objective is to analyze and calibrate the PCC luminometer for the 2025 recorded data by the CMS experiment, working with the PCC method and the van Der Meer (vdM) scans, allowing for a precise measurement of luminosity, and so, having access to more useful information to search for new discoveries.

3 HYPOTHESIS

Based on the analysis corresponding to previous years, a similar or better result is expected. With a systematic uncertainty of 1.4% for 2022, and 1.3% for 2023, it is possible to achieve a precision as good as this, if not an improvement.

4 METHODOLOGY

A pixel cluster is for a group of contiguous pixels activated by a charged particle. The method of choice, PCC, exploits the huge number of pixel in the interior part of the CMS pixel detector, which means that the probability that a single pixel is hit by two charged particles from the same bunch crossing is extremely small.

To ensure accurate and stable luminosity measurement, there is a detector module selection process, where a veto list is made each period and then combined for the entire year. This process involves determining the reliability of each module based on analyzing what is referred as the module weight, which is the change in the ratio of module PCC and total PCC. The veto list consists of modules excluded due to their known and suspected issues that affect the accuracy of the measurement, such as radiation damage, material defects, contamination, along other issues. At the end of said process, around 10% of all modules are used.

The LHC has two main types of runs: physics runs (which could be proton-proton, heavy-ion, or proton-lead collisions,) and callibration runs. As the title of the project suggests, callibration runs are the matter at hand, and consist of more controlled collisions to be able to measure luminosity and other parameters. In these runs, it is necessary to take into consideration a background noise contribution to the PCC rates. Each type of contribution is estimated independently during Super Separation (SS) periods, that are performed to separate two beams a certain distance for a selected period of time. To estimate the background value and its statistical error, the mean value and standard deviation are taken from the distribution resulting of a Y-projection of an average of pixel clusters per event ($\langle PCC \rangle$). Once the noise is taken into account, the data provided can be saved.

To get the van der Meer (vdM) scan data, the pixel detector is read with a trigger of aproximately 50 kHz for about 10 BCIDs of the 140 that collide. The data is then saved distributed in 32 different datasets of events.

To calibrate the luminometer, the vdM scan technique is employed in a special LHC run, usually at the beginning of the year or period. To perform these scans, the separation between proton beams is varied in two dimensions, in separation steps of 100 micrometers. It measures the rates of clusters using the PCC algorithm and the beam parameters during vdM, to determine the calibration constant (σ_{vis}).

The definition of instantaneous luminosity for a single colliding bunch pair is

$$\mathcal{L}(\Delta x, \Delta y) = N_1 N_2 f \int_{-\infty}^{\infty} \rho_1(x, y) \rho_2(x + \Delta x, y + \Delta y) dx dy \quad (3)$$

$$= N_1 N_2 f \int_{-\infty}^{\infty} \rho_1(x) \rho_2(x + \Delta x) dx \int_{-\infty}^{\infty} \rho_1(y) \rho_2(y + \Delta y) dy \quad (4)$$

Where N_1 and N_2 correspond to the number of protons in colliding bunches, $f = 11245.6$ Hz is the frequency of revolution of the LHC, and ρ_i is the proton density distribution of the i -th bunch, assumed Gaussian. For the method to be applicable, it is assumed that the density distributions factorize in the tranverse direction x and y , as shown above.

By integrating over either Δ (e.g. x) and substituting into (4), leads to

$$\int \rho_1(y) \rho_2(y + \Delta y) dy = \frac{\int \mathcal{L}(\Delta x, \Delta y) d(\Delta x)}{N_1 N_2 f} \Rightarrow \mathcal{L}(\Delta x, \Delta y) = \int \rho_1(x) \rho_2(x + \Delta x) dx \int \mathcal{L}(\Delta x', \Delta y) d(\Delta x')$$

and therefore

$$\int \rho_1(x) \rho_2(x + \Delta x) dx = \frac{\mathcal{L}(\Delta x, \Delta y)}{\int \mathcal{L}(\Delta x', \Delta y) d(\Delta x')} \quad (5)$$

Now, from equations (1), (4) and (5), taking $\Delta x = \Delta y = 0$

$$\mathcal{L}(0, 0) = \frac{N_1 N_2 f R(0, 0) R(0, 0)}{\int R(\Delta x', 0) d(\Delta x') \int R(0, \Delta y') d(\Delta y')} = \frac{N_1 N_2 f 2\pi}{\Sigma_x \Sigma_y} \quad (6)$$

where the beam overlap widths $\Sigma_{x,y}$ are defined:

$$\Sigma_{x,y} = \frac{1}{\sqrt{2\pi}} \frac{\int R_{x,y}(\Delta) d\Delta}{R_{x,y}(0)} \quad (7)$$

and once again, from (1), we can define

$$\sigma_{vis} = \frac{R(0, 0)}{\mathcal{L}} = \frac{2\pi \Sigma_x \Sigma_y R(0, 0)}{N_1 N_2 f} \quad (8)$$

The parameter σ_{vis} is known as the calibration constant, and is used to normalize the measured PCC rates so the luminosity can be determined during normal running throughout the data-taking year.

5 SPECIFIC OBJECTIVES

To warrant stable luminosity measurement for Run 3 2025, the set goals are:

- Apply a selection of good modules from the detector: To assure an accurate measurement, a veto list is made, taking only modules with relatively consistent contributions, and then used to only process zero bias PCC data for the vdM analysis.
- Measure the noise in the modules: A calculation of the background contributions, made during selected time windows, to account for secondary particles, and other unwanted parts.
- Set the ideal model adjustment: The generated rates of the scan need to be fitted a mathematical function to extract the parameters needed.
- Measure the beam parameters Σ_i , conducting scans in the x and y directions, determined through curved fitting of the scan data.
- Measure the calibration constant σ_{vis} to normalize the PCC rates.
- Determine the systematic uncertainties on the integrated luminosity: It is necessary to recognize the effects on the beam overlap measurement, and therefore the calculation of σ_{vis} , so corrections are to be applied.

6 EXPECTED RESULTS

The work done in this thesis project is expected to yield the following results:

- Obtain the PCC luminometer calibration constant σ_{vis} for the 2025 data.
- Estimate the background contribution for PCC during vdM calibration program.
- Calculate the parts of the systematic uncertainty corresponding the work group.

7 CALENDAR OF ACTIVITIES

Task / Period	2025-1	Summer 2025	2025-2	2026-1
Practice the programming tools				
Study the literature involved				
Calculate σ_{vis} and its systematic uncertainty				
Estimate the background contribution				
Write the thesis				
Defend the thesis
